Abstract

An important question in assessing 20th century climate change is to what extent have ENSO-related variations contributed to the observed trends. Isolating such contributions is challenging for several reasons, including ambiguities arising from how ENSO itself is defined. In particular, defining ENSO in terms of a single index and ENSO-related variations in terms of regressions on that index, as done in many previous studies, can lead to wrong conclusions. This paper argues that ENSO is best viewed not as a *number* but as an evolving *dynamical process* for this purpose. Specifically, ENSO is identified with the four dynamical eigenvectors of tropical SST evolution that are most important in the observed evolution of ENSO events. This definition is used to isolate the ENSO-related component of global SST variations on a month-by-month basis in the 136-yr (1871-2006) HadISST dataset. The analysis shows that previously identified multi-decadal variations in the Pacific, Indian, and Atlantic oceans all have substantial ENSO components. The long-term warming trends over these oceans are also found to have appreciable ENSO components, in some instances up to 40% of the total trend. The ENSO-unrelated component of 5-yr average SST variations, obtained by removing the ENSO-related component, is interpreted as a combination of anthropogenic, naturally forced, and internally generated coherent multi-decadal variations. Two surprising aspects of these ENSO-unrelated variations are emphasized: 1) a strong *cooling* trend in the eastern equatorial Pacific Ocean, and 2) a nearly zonally symmetric multi-decadal Tropical-Extratropical seesaw that has amplified in recent decades. The latter has played a major role in modulating SSTs over the Indian Ocean.

1. Introduction

Distinguishing anthropogenic from natural climate variations is among the most important problems in climate research today. Three kinds of natural variations need to be considered. Variations of the first kind arise from changes in external radiative forcing associated with insolation changes and volcanic eruptions. Variations of the second kind are generated through internal dynamical mechanisms of coherent long-term variability in the ocean. Natural variations of the third kind, that one may call climate noise, are associated with the incoherent low-frequency imprint of phenomena with shorter time scales. The dominant contributor to this noise is the El Niño - Southern Oscillation (ENSO). ENSO is the largest signal in the climate system on interannual scales, but on longer scales it appears as noise. Because its spectrum has a long low-frequency tail, fluctuations in the timing, number, and amplitude of individual El Niño and La Niña events within, say, 50-yr intervals can give rise to substantial 50-yr trends. Such trends are inherently unpredictable. Anthropogenic and naturally forced climate changes, as well as coherent (and therefore potentially predictable) internally generated long-term climate variations, have to be measured against this ENSO-related noise background to appreciate their true significance around the globe.

The problem of estimating and removing ENSO-related variations from climate records has been addressed in many previous studies using a variety of methods. Penland and Matrosova (2006; hereafter PM06) discussed several difficulties with these methods. A common approach is to use a frequency band-pass filter passing periods between approximately 2 and 6 years to identify the ENSO-related variations (e.g., Parker et al.

2007; Folland et al. 1999; Lau and Weng 1999; Zhang et al. 1997). This makes the strong assumption that all of the SST variability in the chosen band, and none outside it, is associated with ENSO. This is clearly unsatisfactory, given the broadband nature of ENSO dynamics. It is not an accident that a substantial portion of decadal and longer-term climate variability has been found to be ENSO-like (e.g., Zhang et al. 1997; Alexander et al. 2002; Newman et al. 2003; Schneider and Cornuelle 2005).

Another class of ENSO-removal methods involves linear regression on the time series of some ENSO index, such as the Niño-3.4 SST index, the equatorial Pacific Cold-Tongue index, the Southern Oscillation index, or the amplitude (i.e. Principal Component, PC) of the dominant EOF pattern of tropical SST variability (e.g., Robock and Mao 1995; Kelly and Jones 1996; Cane et al. 1997; Angell 2000; Chiang and Vimont 2004; Wheeler and Hendon 2004). The index time series is sometimes also band-pass filtered as an initial processing step. One immediate difficulty with using such single-index definitions of ENSO is that no ENSO-unrelated variations can occur in that index. If one uses the Niño-3.4 SST index, for example, then no "global warming" signal can ever occur in the Niño-3.4 region, *by definition*. This is also clearly unsatisfactory, given climate model predictions of a significant change in this region in response to greenhouse gas increases (e.g. Meehl et al. 2007).

There are other difficulties with following simple regression approaches, as noted by PM06. One is that not all ENSO-related variations occur in step around the globe (Alexander et al. 2002, and references). For example, ENSO-related SST anomalies in

the tropical Indian and Atlantic Oceans typically peak several months after those in Niño-3.4 (e.g., Covey and Hastenrath 1978; Lanzante 1996; Kumar and Hoerling 2003). Using time-lagged regressions lessens the problem (Robock and Mao 1995; Angell 2000), but assumes that all frequency components are maximally correlated at the same lag. Regression onto the dominant SST PC time series is additionally problematic: it assumes that ENSO is associated with the waxing and waning of a single SST EOF pattern, which is inconsistent with observed ENSO dynamics (e.g. Penland and Sardeshmukh 1995, hereafter PS95; Wallace et al 1998; Vimont 2005). Some investigators (e.g., Enfield and Mestas-Nuñez 1999) have addressed this limitation by regressing global SSTs onto the complex PC time series of the dominant complex EOF of global SSTs, which is associated with two SST patterns. This is a step in the right direction, but ignores the fact that observed ENSO evolution involves at least six patterns (PS95; Penland and Matrosova 1998; PM06).

Finally, an often overlooked aspect of almost all traditional ENSO-removal methods is the implicitly assumed, but physically unjustified, orthogonality of the ENSO-related and ENSO-unrelated variations. Consider, for concreteness, the decomposition of the anomalous tropical SST state vector $\mathbf{X}(t)$ into its ENSO-related and ENSO-unrelated parts as:

$$\mathbf{X}(t) = \mathbf{x}_e(t) + \mathbf{x}_n(t), \quad (1)$$

and a similar decomposition of the rest of the anomalous climate state vector $\mathbf{Y}(t)$ as :

$$\begin{aligned} \mathbf{Y}(t) &= \mathbf{y}_e(t) + \mathbf{y}_n(t) \\ &\approx \mathbf{A} \mathbf{x}_e(t) + \mathbf{y}_n(t), \end{aligned} \quad (2)$$

in which, in the simplest approximation, one may assume \mathbf{y}_e to be linearly related to \mathbf{x}_e . We stress again that there is no physical basis for assuming the orthogonality of \mathbf{x}_n and \mathbf{x}_e , or of \mathbf{y}_n and \mathbf{y}_e . However, the common practice of using an \mathbf{A} to estimate \mathbf{y}_e that is based on regressions of $\mathbf{Y}(t)$ on $\mathbf{x}_e(t)$ *enforces* an orthogonality of \mathbf{y}_n and \mathbf{y}_e . Note also that \mathbf{y}_n and \mathbf{x}_n need not be related (if they are related at all) through the same \mathbf{A} operator that links \mathbf{y}_e and \mathbf{x}_e . But even if they were so related, and even if \mathbf{x}_n were orthogonal to \mathbf{x}_e , this would still not make \mathbf{y}_n orthogonal to \mathbf{y}_e unless \mathbf{A} were an orthogonal operator (i.e. $\mathbf{A}^T \mathbf{A} = c\mathbf{I}$), for which there is no physical justification.

PM06 proposed an alternative method for isolating \mathbf{x}_e , based on the analysis of PS95, who had shown that the evolution of tropical SST anomaly fields $\mathbf{x}(t)$ in a truncated EOF space is well approximated over several seasons by the linear equation $\mathbf{x}(t+\tau) = \mathbf{G}(\tau) \mathbf{x}(t) + \boldsymbol{\epsilon}$, where $\mathbf{G}(\tau) = \exp(\mathbf{L}\tau)$, \mathbf{L} is a constant matrix, and $\boldsymbol{\epsilon}$ is a noise vector. PS95 also showed that the development of ENSO events is well-approximated by the evolution $\mathbf{x}(t) = \mathbf{G}(t)\mathbf{x}(0)$ from an "optimal" initial SST anomaly field $\mathbf{x}(0) = \boldsymbol{\phi}_1$ identified with the dominant right singular vector $\boldsymbol{\phi}_1$ of $\mathbf{G}(\tau=7 \text{ months})$. This evolution leads to a mature ENSO pattern and subsequent decay as observed. PS95 stressed the pattern-changing aspect of this evolution; $\boldsymbol{\phi}_1$ is distinct from the mature ENSO pattern it evolves into. Furthermore, this pattern-changing evolution occurs almost entirely within a linear vector space spanned by a three-mode subset $\{\mathbf{U}_k\}$ of the eigenmodes of \mathbf{L} , i.e., $\boldsymbol{\phi}_1$ is well approximated by a linear combination of this subset. PM06 exploited this fact to define the evolving ENSO-related part $\mathbf{x}_e(t)$ of tropical SST series $\mathbf{x}(t)$ as $\mathbf{x}_e(t) = \sum \alpha_k(t) \mathbf{U}_k$.

Our principal goal in this paper is to isolate the ENSO-related component of global SST variations on a month-by-month basis in the 136-yr (1871-2006) HadISST dataset (Rayner et al. 2003) using an extended form of PM06's patterns-based filter. We define the extratropical portions \mathbf{y}_e of the ENSO-related extratropical SST anomaly fields as those that are linked to the tropical portions \mathbf{x}_e through the so-called “atmospheric bridge” (Alexander et al. 2002). This link is established through relatively rapid extratropical atmospheric responses to tropical SST changes, and subsequent forcing by the associated altered surface heat fluxes of extratropical SST changes. We estimate the effective “bridge” operator \mathbf{A} empirically, from linear regressions of extratropical SSTs onto tropical SSTs on interannual time scales, and separately for each month in the annual cycle. (As explained later, this avoids the problem of the false imposition of orthogonality between \mathbf{y}_e and \mathbf{y}_n alluded to above). We then use this operator to estimate the ENSO-related extratropical SST anomaly field \mathbf{y}_e associated with the ENSO-related tropical field \mathbf{x}_e in each month of the 136-yr dataset. Merging this extratropical field with the tropical field yields the ENSO-related global SST anomaly field in each month of the dataset.

Removing the ENSO-related anomaly fields from the full SST anomaly fields can substantially alter one’s perception of multi-decadal SST variability and long-term SST trends around the globe, as will become evident in the following sections. Figure 1 provides a preview. The black curve shows the time series of globally averaged 10-yr running mean SST anomalies in the HadISST dataset. The red curve shows the same

series after its ENSO-related components are removed. The modification is appreciable, not just on decadal scales but even to the long-term trend. The original series has an 1871-2006 trend of ~ 0.05 K/decade, consistent with Rayner et al.'s (2003) estimate. After removal of the ENSO-related components, that trend is reduced to ~ 0.03 K/decade.

Section 2 provides further justification and some important details of our method for isolating \mathbf{x}_e using a dynamical ENSO patterns filter. Our preference for a filter based on *dynamical* rather than *statistical* ENSO patterns is partly motivated by evidence that the basic *dynamics* of ENSO, as encapsulated in those eigenmodes of \mathbf{L} that are most important in the evolution of ENSO events, have remained nearly constant over the past 136 years, even if the *statistics* of ENSO have not. Indeed a statistical-patterns based filter would require an even stronger assumption that the covariance structure of the full tropical SST anomaly fields $\mathbf{X}(t)$, and not just their ENSO-related parts $\mathbf{x}_e(t)$, have remained constant over the past 136 years, which is harder to justify in a changing climate. Section 3 describes our procedure for estimating the extratropical portions \mathbf{y}_e of the ENSO-related SST anomaly fields. Section 4 presents some surprising results obtained after removing the ENSO-related anomaly fields from the full anomaly fields in the HadISST dataset, including the effects on long-term trends and on the dominant global patterns of low-frequency (5-yr running mean) SST variations. Evidence that the basic dynamics of ENSO have not changed appreciably in the last 136 years is presented in Section 5, and a discussion and concluding remarks follow in Section 6.

2. Tropical Dynamical ENSO Patterns Filter (EPF)

As mentioned above, the EPF developed by PM06 determines the ENSO-related portion $\mathbf{x}_e(t)$ of tropical SST anomaly fields as $\mathbf{x}_e(t) = \Sigma \alpha_i(t) \mathbf{U}_i$, where $\{\mathbf{U}_i\}$ is a particular subset of the eigenmodes of the matrix \mathbf{L} in the linear model

$$\mathbf{x}(t + \tau) = \exp(\mathbf{L}\tau) \mathbf{x}(t) + \varepsilon = \mathbf{G}(\tau) \mathbf{x}(t) + \varepsilon \quad (3)$$

of tropical SST evolution over several seasons. \mathbf{L} is estimated using the observed lag-covariance matrices $\mathbf{C}(\tau) = \langle \mathbf{x}(t+\tau) \mathbf{x}(t)^T \rangle$ at two lags, $\tau = 0$ and $\tau = \tau_o$, as

$$\mathbf{L} = \frac{1}{\tau_o} \ln \{ \mathbf{C}(\tau_o) \mathbf{C}(0)^{-1} \} , \quad (4)$$

following the Linear Inverse Modeling (LIM) procedure described, e.g., in Penland and Magorian (1993) and PS95. As discussed in those papers, a consistency requirement for the validity of (3) is that this estimate of \mathbf{L} be independent of the particular choice of τ_o . In this study, we used $\tau_o = 3$ months as in PM06, and the 1949-2004 monthly HadISST SST data to estimate the $\mathbf{C}(0)$ and $\mathbf{C}(\tau_o)$ matrices. The choice of the second half of the HadISST dataset for this purpose was partly motivated by the fact that 1949 marks a significant increase in the input data density used in constructing the dataset (Rayner et al. 2003), and partly by a need to leave an “independent” first half for assessing the dynamical stationarity of \mathbf{L} . As in PM06, \mathbf{L} was estimated using SSTs in the entire tropical domain 30°N-30°S. Three month running-mean anomalies were formed at each grid point as differences from the 1949-2004 monthly-average annual cycle. The 1° data were spatially smoothed using a 3°-latitude, 5°-longitude boxcar smoother. These smoothed fields were then projected on a truncated space of 20 SST EOF patterns, retaining about 89% of the SST variance. The time varying coefficients of these 20 EOFs,

i.e., the 20 PC time series, define the truncated 20-component tropical SST vector $\mathbf{x}(t)$ used for isolating $\mathbf{x}_e(t)$ in this study.

Extensive sensitivity and cross-validation exercises were performed for all EOF truncations from 2 to 30 before settling on the choice of 20 EOFs, using the skill of tropical SST hindcasts based on (3) as a guiding criterion. This was done by excluding, in turn, each of 8 contiguous 7-yr segments from the data, estimating \mathbf{L} from the remaining 49 years, and then performing hindcasts in the excluded 7-yr segment. The best average hindcast skill was obtained for a 20 EOF truncation, in terms of both anomaly pattern correlation skill and root mean square error over the domain.

Maps of the local anomaly correlation skill for forecast lead times of $\tau = 3, 6, 9$, and 12 months are shown in Fig. 2. They show that (3) successfully captures the SST evolution in all tropical ocean basins at lead times of up to a year. Nearly identical skills were obtained (not shown) with \mathbf{L} operators estimated using $\tau_0 = 6$ months and $\tau_0 = 9$ months in (4), further attesting to the validity of (3).

As in PS95, we found that ENSO development is well described by the evolution $\mathbf{x}(t) = \mathbf{G}(t)\mathbf{x}(0)$ from an "optimal" initial condition $\mathbf{x}(0) = \phi_1$ to a mature ENSO condition $\mathbf{x}(8) = \mathbf{G}(8)\phi_1 = \gamma_1\psi_1$ after 8 months, where ϕ_1 and ψ_1 are the normalized dominant right and left singular vectors of $\mathbf{G}(8 \text{ months})$, respectively, and γ_1 is the associated singular value. The spatial patterns of ϕ_1 and ψ_1 are shown in Fig. 3. They strongly resemble those obtained in previous studies using different datasets and domains (PS95, Penland and

Matrosova 1998, PM06, Alexander et al. 2008). Figure 3c confirms that the projection of $\mathbf{x}(t)$ on ϕ_1 is a good predictor of Niño-3.4 SST eight months later. The 8-month lead correlation of 0.65 is much higher than, e.g., the 8-month lead correlation of -0.2 obtained using the projection of $\mathbf{x}(t)$ on the dominant SST EOF as the predictor.

The particular insight of PM06 was to use the development from ϕ_1 as a basis for *defining* ENSO as a stochastically perturbed evolving dynamical *process*. Specifically, they defined the evolving ENSO-related component $\mathbf{x}_e(t)$ of evolving tropical SST anomaly fields $\mathbf{x}(t)$ as $\mathbf{x}_e(t) = \Sigma \alpha_k(t) \mathbf{U}_k$, where $\{\mathbf{U}_k\}$ is that subset of the eigenvectors of \mathbf{L} which contributes most to the structure of ϕ_1 . In other words, the ENSO-related evolution is defined as the projection of equation (3) in this eigenvector subspace. Importantly, this does not require ENSO events to develop *precisely* from ϕ_1 in all cases, which of course they do not.

The evolution associated with each ENSO-relevant eigenmode of \mathbf{L} may be conveniently expressed and visualized in terms of the corresponding eigenmodes of $\mathbf{G}(\tau) = \exp(\mathbf{L}\tau)$. The eigenvectors of $\mathbf{G}(\tau)$ are identical to the eigenvectors \mathbf{U}_k of \mathbf{L} , and the eigenvalues are $\exp(\beta_k \tau)$, where $\beta_k = \sigma_k + i\omega_k$ are the corresponding eigenvalues of \mathbf{L} . Since \mathbf{G} is real, its eigenvectors and eigenvalues occur in complex conjugate pairs. These pairs can be combined into a single real modal solution $\mathbf{x}_k(t)$ as

$$\mathbf{x}_k(t) = \{\mathbf{a}_k \cos \omega_k t + \mathbf{b}_k \sin \omega_k t\} \exp(\sigma_k t) \quad (5)$$

where \mathbf{a}_k and \mathbf{b}_k are real vectors with $\mathbf{a}_k^T \mathbf{b}_k = 0$, $\mathbf{a}_k^T \mathbf{a}_k = 1$, and $\mathbf{b}_k^T \mathbf{b}_k \geq 1$ (see e.g., Borges and Sardeshmukh 1995). Without the exponential decay factor, the mode traces out an ellipse in the space spanned by \mathbf{a}_k and \mathbf{b}_k from the minor axis \mathbf{a}_k to the major axis \mathbf{b}_k , then to $-\mathbf{a}_k$ and $-\mathbf{b}_k$, and then back to \mathbf{a}_k . The e -folding decay time of each mode is defined as $-1/\sigma_k$, its period as $2\pi/\omega_k$, and its effective time scale as $1/|\beta_k|$.

We determined the ENSO-relevant subset $\{\mathbf{U}_k\}$ objectively, as follows. First, the mode of \mathbf{L} with the longest effective time scale (associated with a long decay time scale of ~ 40 months) was identified and excluded. The remaining modes were ranked by the magnitude of the inner product of their corresponding adjoint eigenvector \mathbf{V}_k (i.e., the eigenvector of \mathbf{L}^T with the same eigenvalue) with ϕ_1 . Then, starting with the mode having the largest inner product and longest effective time scale, a truncated $\mathbf{G}(8)$ operator was constructed using only this eigenmode. Its dominant right and left singular vectors and singular value were compared with the ϕ_1 , ψ_1 , and γ_1 obtained from the full $\mathbf{G}(8)$ operator. If the pattern correlations exceeded 0.5, the mode was included in the ENSO-relevant subset; if not, the procedure was repeated for succeeding modes in the ranked list until they did. The criterion for including additional modes in the subset was whether their inclusion improved the approximation to ϕ_1 , ψ_1 , and γ_1 . A mode was included if the pattern correlations with ϕ_1 and ψ_1 increased, and the singular value also increased, or decreased by less than 5% of γ_1 . Applying this procedure yielded a total of 4 ENSO-relevant eigenmodes. Remarkably, we found this selection algorithm to be completely insensitive to the order of consideration of the subsequent modes when the threshold

pattern correlation for membership of the first member of the subset was set at 0.5 or higher.

The spatial structures of the four ENSO-relevant eigenmodes are shown in Fig. 4, along with their effective time scale, period, and decay time. ENSO Mode 1 corresponds very closely to PS95's “46 month” mode. The other modes are difficult to compare directly with previous studies, since they showed the real and imaginary parts of the modes at arbitrary phases, rather than at their “least energetic” and “most energetic” phases as in (5).

Our ENSO Modes 1 and 2 are readily identifiable with canonical ENSO evolution, each developing from weak warm anomalies in the eastern equatorial Pacific into strong warm anomalies there 4 to 12 months later. Modes 1, 2, and 4 are associated with the previously identified quasi- 4-yr, 2-yr, and 5- to 6-yr periodicities of ENSO (PS95; Moron et al. 1998). Modes 3 and 4 have longer periods, but relatively fast decay times, so one does not expect to see more than about a quarter of the implied oscillation in individual realizations. Even so, these modes contribute to the overall evolution from ϕ_1 to ψ_1 . Together with Modes 1 and 2, they help to explain the westward and eastward propagation of ENSO events (PS95), and also ENSO events of different “flavors” (e.g., Fu et al. 1986).

Having determined the ENSO-relevant eigenmodes, the ENSO-related parts $\mathbf{x}_e(t)$ of the tropical SST anomaly fields $\mathbf{x}(t)$ were determined as

$$\mathbf{x}_e(t) = \sum_{k=1}^4 \alpha_k(t) \mathbf{U}_k = \sum_{k=1}^4 [\mathbf{V}_k^T \mathbf{x}(t)] \mathbf{U}_k \quad (6)$$

and the ENSO-unrelated parts as the departures

$$\mathbf{x}_n(t) = \mathbf{X}(t) - \mathbf{x}_e(t) \quad (7)$$

of the *full* (i.e. untruncated) SST anomaly fields $\mathbf{X}(t)$ from $\mathbf{x}_e(t)$.

3. Extratropical ENSO-related variations

We define the ENSO-related parts $\mathbf{y}_e(t)$ of the extratropical SST anomaly fields $\mathbf{Y}(t)$ to be those that are linearly linked to $\mathbf{x}_e(t)$ as $\mathbf{y}_e(t) = \mathbf{A} \mathbf{x}_e(t)$, where \mathbf{A} is a linear "atmospheric bridge" operator. As stated earlier, this atmospheric bridge is established through relatively rapid extratropical atmospheric responses to tropical SST changes, and subsequent forcing by the associated altered surface heat fluxes of extratropical SST changes. We estimated \mathbf{A} empirically, but bearing in mind the discussion following equation (2), not by regressing $\mathbf{Y}(t)$ on $\mathbf{x}_e(t)$ but instead by regressing band-pass filtered variations $\mathbf{y}_b(t)$ of $\mathbf{Y}(t)$ in the 2- to 72-month period band on similarly filtered simultaneous variations $\mathbf{x}_b(t)$ of $\mathbf{X}(t)$. We did this separately for 3-month seasons centered on each month of the annual cycle, obtaining and using 12 distinct \mathbf{A} matrices in all. Having determined $\mathbf{y}_e(t)$ using these \mathbf{A} matrices, we then determined the ENSO-unrelated parts $\mathbf{y}_n(t)$ as $\mathbf{y}_n(t) = \mathbf{Y}(t) - \mathbf{y}_e(t)$.

The rationale for the above procedure was as follows. First, since we *define* $\mathbf{y}_e(t)$ to be the relatively fast extratropical SST response to $\mathbf{x}_e(t)$ through the atmospheric bridge mechanism, we expect the matrix \mathbf{A} linking them to be the same as that linking *all*

relatively fast extratropical SST variations to *all* relatively fast tropical SST variations. Hence our estimation of \mathbf{A} through regressions of $\mathbf{y}_b(t)$ on $\mathbf{x}_b(t)$. An important benefit of using such an \mathbf{A} is that we do not automatically impose a false orthogonality between $\mathbf{y}_e(t)$ and $\mathbf{y}_n(t)$. Second, since \mathbf{A} is essentially a matrix of sensitivities of the fast extratropical SST responses to tropical SST changes, then given that those sensitivities vary from season to season (Newman and Sardeshmukh 1998; Barsugli et al. 2006), it is desirable to use a seasonally varying \mathbf{A} for realistic estimations of \mathbf{y}_e .

To minimize edge effects when merging $\mathbf{y}_e(t)$ with $\mathbf{x}_e(t)$ to construct global ENSO-related SST anomaly fields, we actually determined \mathbf{A} as the appropriate submatrix of a larger regression matrix $\tilde{\mathbf{A}}$ linking the *global* band-pass filtered SSTs $\tilde{\mathbf{y}}_b$ to \mathbf{x}_b . We estimated this $\tilde{\mathbf{A}}$ separately for each 3-month season in truncated spaces of the seasonally-dependent EOFs of \mathbf{x}_b and $\tilde{\mathbf{y}}_b$, retaining 20 and 15 EOFs, respectively, of these fields in each season. The truncation to 15 EOFs was chosen after an extensive cross-validation exercise using the 1949-2004 data, withholding 8 years of data per cross-validation set for all EOF truncations between 2 and 28. The 15-EOF truncation yielded the largest cross-validated hindcast skill of \mathbf{y}_b given \mathbf{x}_b , in terms of both local anomaly correlation and root-mean-square error averaged over all seasons and extratropical regions. Figure 5 shows, for this optimal 15-EOF truncation, the fractional variance of \mathbf{y}_b explained by \mathbf{x}_b , averaged over all seasons. The tropical variations evidently account for more than 10% of the extratropical variance almost everywhere, and more than 50% of the variance over substantial areas.

To generate the global ENSO-related fields, we first generated a preliminary set of global fields $\tilde{\mathbf{y}}_e = \tilde{\mathbf{A}} \mathbf{x}_e$, which were very close but not identical to \mathbf{x}_e in the tropics. We then created the final set $\mathbf{z}_e(t)$ by merging $\tilde{\mathbf{y}}_e$ with \mathbf{x}_e as

$$\mathbf{z}_e(t) = (1 - \alpha) \tilde{\mathbf{y}}_e(t) + \alpha \mathbf{x}_e(t) \quad (8)$$

using a cosine taper function α decreasing from a constant value of 1 equatorward of 24.5° to zero poleward of 30.5° . The global ENSO-unrelated variations were then determined as departures of the full global SST anomaly fields $\mathbf{Z}(t)$ from $\mathbf{z}_e(t)$ as

$$\mathbf{z}_n(t) = \mathbf{Z}(t) - \mathbf{z}_e(t) . \quad (9)$$

4. Results

We now present the results obtained after removing the ENSO-related component from the full SST anomaly fields in the HadISST dataset, including the effects on long-term trends and on the dominant global patterns of low-frequency (5-yr running mean) SST variations. We also consider how removing the ENSO-related component affects the time series of various low-frequency SST indices, such as the Atlantic Multidecadal Oscillation (AMO) index, associated with climate variability and change.

4.1 Long-term SST Trends

Figure 6a shows that almost all ocean basins have warmed over the 1871-2006 period. This is in general agreement with other estimates (e.g., Hansen et al. 2006). The map shows that the warming has not been spatially uniform. The warming trend pattern for a shorter period of 1901-2006 is similar to that in Fig. 6a, but with a slightly larger amplitude (not shown, but see e.g., Hegerl et al. 2007). The ENSO-related contribution to the 1871-2006 trend, obtained using (8), is shown in Fig. 6b. Not unexpectedly, it is

largest in the eastern tropical Pacific and negative in parts of the north and south Pacific, consistent with the "low-frequency tail" of ENSO. More surprisingly, it also accounts for an appreciable fraction of the total warming trend in Fig. 6a in many other regions.

The ENSO-unrelated part of the 1871-2006 trend, obtained using (9), is shown in Fig. 6c. It accounts for a large fraction of the total warming trend, especially outside the tropics. The situation is much less clear in the tropics, especially in the eastern tropical Pacific where Fig. 6c shows a large ENSO-unrelated *cooling* trend. This result is surprising, but is broadly consistent with the results of Cane et al. (1997) and Lau and Weng (1999) obtained using different observational datasets and analysis techniques. A cooling trend in this region has also been hypothesized to be a coupled response to uniform radiative forcing (Clement et al. 1996; Cane et al. 1997). Notably, such a cooling response is not produced in comprehensive coupled climate models, although it has been found in ocean models subjected to uniform radiative and enhanced absorbed shortwave forcing (Seager and Murtugudde 1997, Sweeney et al. 2005).

As is well known, the global warming trend since the late 19th century has not been constant but has varied considerably on multi-decadal time scales (e.g., Hegerl et al. 2007). It is therefore important to construct versions of Fig. 6 for more recent periods in which the warming appears to have accelerated. Figure 7 shows the total, ENSO-related, and ENSO-unrelated SST trends over the 1949-2006 period in the same format as Fig. 6 and on the same scale. The generally larger trends in Fig. 7a compared to Fig. 6a are consistent with previous estimates using different datasets (e.g., Knutson et al. 2006).

Nonetheless, the same overall conclusions may be drawn from Fig. 7 concerning the relative contributions of the ENSO-related and ENSO-unrelated trends to the total trend even over this shorter more recent period. This is partly because the ENSO-related trend is also larger in Fig. 7b than in Fig. 6b. Note that it remains generally reminiscent of the "low-frequency tail" of ENSO.

The ENSO-unrelated part of the 1949-2006 trend is shown in Fig. 7c. Its generally similar pattern but weaker amplitude compared to the observed trend in Fig. 7a suggests that it accounts for approximately 2/3 of the observed trend in most regions. The interesting ENSO-unrelated cooling trend in the eastern equatorial Pacific now appears with even larger amplitude than in Fig. 6c, but is more meridionally confined. It is tempting to speculate that such a cooling is dynamically consistent with an enhancement of surface easterlies and equatorial upwelling over the eastern Pacific in response to the strong ENSO-unrelated recent warming of the Indian and west Pacific oceans.

4.2 Dominant patterns of low-frequency SST variations

Linear trend maps such as Figs. 6 and 7 fail to capture the detailed structures of observed multidecadal and longer-term variations (e.g., Parker et al. 2007, and references). An EOF analysis can be more revealing in this regard. The left panels of Fig. 8 show the two leading EOFs and associated PCs of 5-year running mean HadISST anomalies in the 1871-2006 period. The first EOF of such long-term SST variations is often identified with global warming (Parker et al. 2007). Note that it is similar, but not identical, to the long-term trend pattern in Fig. 6a. The second EOF is often identified with "ENSO-like

decadal variability" (Zhang et al. 1997), a global signature of the Pacific Decadal Oscillation, or the Interdecadal Pacific Oscillation (Parker et al. 2007). It is strongly reminiscent of the "low-frequency tail" of ENSO, and has indeed been argued to be such in previous studies (e.g., Alexander et al. 2002; Newman et al. 2003, Schneider and Cornuelle 2005).

The two leading EOFs and associated PCs of the ENSO-unrelated 5-yr running mean SST variations are shown in the right panels of Fig. 8, in the same format as the left panels. The first EOF of these ENSO-unrelated variations is generally very similar to first EOF of the total variations in Fig. 8a, but not in the tropics. In particular, the eastern Pacific cooling emerges as an important part of this leading pattern, of which there is only a hint in Fig. 8a.

The second EOF of the ENSO-unrelated variations, shown in Fig. 8d, is strongly suggestive of nearly zonally symmetric multi-decadal Tropical-Extratropical See-Saw (TESS). A very similar pattern was identified by Livezey and Smith (1999) as importantly related to North American climate variations, but was interpreted by them as a "global climate change signal" associated with anthropogenic warming. Although the PC time series in Fig. 8d does show a strong "trend" from the 1950s to the 1990s, the multi-decadal oscillatory nature of the variation is more obvious in the full record. The tropical aspect of this variation was also identified and interpreted as a tropical "trend" pattern by PM06, but again using a shorter record. As in that study, the PC time series in Fig. 8d has a parabolic shape from the 1950s to the present; however, there is no trend

over the full record. These variations appear to be related to global circulation and precipitation changes claimed by Baines and Folland (2007) to be associated with an “abrupt climate shift” in the late 1960s, and to changes in Sahel rainfall (see also PM06). A relatively sudden upturn in the late 1960s is also evident in our PC time series in Fig. 8d.

Overall, Fig. 8 shows that one can get quite a different impression of low-frequency SST variations around the globe in the last 136 years after their ENSO-related components are removed. We interpret the ENSO-unrelated variations as representing a combination of anthropogenic, naturally forced, and internally generated coherent multi-decadal variations. It is far beyond the scope of this study to attempt a further split into these three component variations. Nonetheless, it is tempting to associate EOF-1 of the ENSO-unrelated variability with “forced” and EOF-2 with “natural internal” variability, mainly because PC-1 has a strong long-term trend and PC-2 has no trend. If EOF-2 is indeed indicative of a natural multi-decadal tropical-extratropical see-saw, then its general upward trend from the 1950s to the 1990s may have been misinterpreted in the climate community as an accelerated “forced” trend, and its sharp upturn in the 1960s as an anthropogenic abrupt climate shift. Its relatively large amplitude over the Indian ocean (compared to EOF-1) suggests that it has played a major role in modulating Indian ocean SSTs over the last half century, which have also been implicated in several climate change attribution studies (e.g., Hurrell et al. 2004).

4.3 SST-based climate indices

SSTs averaged over various large representative areas are widely used as indices of climate variability. The global ocean SST average is one such commonly used measure (Hegerl et al. 2007). As already shown in Fig. 1, removing its ENSO-related component reduces its 136-year warming trend from ~ 0.05 K/decade to ~ 0.03 K/decade. This is also consistent with Angell's (2000) analysis of tropospheric air temperatures, who found that about 2/3 of the overall trend in his data was ENSO-unrelated.

The effects of removing ENSO-related components from two other climate indices are illustrated in Fig. 9. The West Pacific/Indian Ocean Warm Pool encompasses the area of warmest SSTs on the planet. Global mean surface temperature and precipitation are particularly sensitive to SST changes in this area (Barsugli et al. 2006). The black curve in Fig. 9a shows the 10-year running mean time series of SSTs averaged over the Warm Pool. Removing its ENSO-related components produces the ENSO-unrelated red curve. It is remarkable that the ENSO-unrelated time series shows a slight cooling trend from ~ 1900 to the mid-1970s, followed by an abrupt warming and stabilization. The ENSO-related variations have clearly contributed substantially to the observed full time series, contributing a warming influence in the early 20th century, a cooling influence in the 1980s, and again a warming influence in the early 21st century.

Another climate index that has received considerable attention is the index of the Atlantic Multidecadal Oscillation (AMO, e.g., Enfield and Mestas-Nuñez 1999; Delworth and Mann 2000), especially for its purported links to Atlantic hurricane variability

(Goldenberg et al. 2001), global drought (McCabe and Palecki 2006), and European climate (Parker et al. 2007). It has been suggested that this oscillation may be natural and predictable (Knight et al. 2005). Here, we define the AMO index, following Enfield et al. (2001), as the linearly-detrended area-average North Atlantic SST. Its 10-year running mean time series is shown as the black curve in Fig. 9b. The multidecadal variations discussed in numerous previous studies are evident and consistent with other datasets and AMO definitions (see Delworth and Mann 2000 for a review). The version of the AMO index with its ENSO-related components removed is shown as the red curve. It is not aligned precisely with the full index series after about 1990, but is extremely close; to that extent, it confirms that much of the recent increase in detrended North Atlantic SSTs is only weakly ENSO-related. In other periods, however, the discrepancy between the black and red curves is indicative of a considerable ENSO influence, such as contributing to an enhancement of the oscillation from ~1900 to the 1950s. Insofar as such ENSO contributions are climate noise, these results suggest that modeling studies of North Atlantic climate variations (e.g., Delworth and Mann 2000; Knight et al. 2005) may have greater success comparing their simulated variations with the ENSO-unrelated variations shown here than with the full observed variations.

5. Constancy of ENSO dynamics

The overarching conclusion of this study is that both long-term trends and multi-decadal variations over the last 136 years in the Pacific, Indian, and Atlantic oceans have had substantial ENSO-related components. Because our estimates of these components are somewhat larger than reported in previous studies, and to that extent are also somewhat

surprising, it is necessary to reassess some of the assumptions of our analysis. One particular assumption, which we maintain is much weaker than made in other ENSO-removal studies but is nevertheless still an assumption, is that the *dynamics* of ENSO have remained roughly constant over the last 136 years even if their statistics have not. By this we mean that the ENSO-relevant eigenmode subset of the tropical dynamical evolution operator \mathbf{L} , shown in Fig. 4, has remained roughly the same in the last 136 years. In the following, we pursue two different lines of evidence in support of this claim, specifically that \mathbf{L} itself has not shown a systematic trend over the last 136 years.

It has long been thought that one of the most important controlling influences on ENSO dynamics is ΔT_{E-W} , the east-west SST gradient across the tropical Pacific basin (Bjerknes 1969; Neelin et al. 1998 and references; Sun 2003). Figure 10 shows that although ΔT_{E-W} has varied throughout the record, with 10-year averaged values of up to 25% larger or smaller than the 1871-2006 average, it has not shown a systematic trend over the entire record. To be sure, there is evidence of an upward "trend" after 1900 (Cane et al. 1997) and in the most recent 50 years (Zhang and McPhaden 2006), but it is clear they are part of long-term variability with no obvious overall trend.

If the relatively modest long-term variations in ΔT_{E-W} were important in modulating ENSO variability, one might expect such a modulation to be evident in the variance of ENSO-indices such as Niño-3.4 SSTs. The gray shaded curve in Fig. 10 shows the time series of 2-6 year variance in Niño-3.4 from the HadISST dataset, produced following the method of Torrence and Compo (1998). While there are hints of an association, say

during the 1890's and in the most recent decades, there are also periods of large Niño-3.4 variance co-existing with those of weak gradients, such as the early 1900s. These variations of Niño-3.4 variability are consistent with those of other ENSO indices such as Niño-3, the SOI (Torrence and Webster 1999), and central Pacific rainfall (Kestin et al. 1998).

It has recently been suggested that the interaction of the subtropical ocean with the equatorial ocean through “oceanic tunnels” may also be important in modulating ENSO dynamics (e.g., Seager and Murtugude 1997; Kleeman et al. 1999; Shin and Liu 2000; Sun et al. 2004; Solomon et al. 2008). A simple proxy for this effect is the SST gradient between the north subtropical and tropical Pacific SSTs ΔT_{N-S} . The blue curve in Fig. 10 shows that decadal variations in this gradient have been less than 20% of the long-term mean. Again, there is no obvious correspondence with changes of Niño-3.4 SST variance. Although large changes of ΔT_{N-S} could be expected to impact ENSO (Collins 2000; Sun et al. 2004), the observed changes have apparently not been large enough in this regard. As such, they have probably not altered the tropical dynamics represented in **L**. They do not appear to be related consistently to variations in the statistics of Niño-3.4 SSTs, nor to those of other ENSO indices (Wang and Wang 1996; Torrence and Compo 1998; Kestin et al 1998; Torrence and Webster 1999).

Another way of assessing the near constancy of **L** is to ask to what extent does the forecast skill of the model (3) vary over the 136 years of record if one uses a constant **L** to make the forecasts. Figure 11 shows the 136-yr time series of the pattern correlation of

the observed and predicted seasonal tropical SST anomaly fields for various forecast lead times. Recall that the model (i.e. the \mathbf{L} operator) was developed using the 1949-2004 data at a 3-month lag. Therefore all comparisons for 1871-2006 at 6-month and 12-month lags are independent tests, as is the forecast skill for 1871-1948 at the 3-month lag. The relative constancy of the forecast skill is remarkable. The drop in skill between the 1910s and 1950s may reflect reduced observation availability during the World Wars, but may also be associated with decreased ENSO variability itself in the period as reflected in several ENSO indices (Wang and Wang 1996; Torrence and Compo 1998; Kestin et al 1998; Torrence and Webster 1999), and illustrated for Niño-3.4 SSTs in Fig. 10.

Taken together, the evidence in Figs. 10 and 11 suggests that the tropical ocean dynamics encapsulated in \mathbf{L} have not changed appreciably in the last 136 years. It is of course true that for sufficiently large changes in the basic state, such as represented in ΔT_{E-W} or ΔT_{N-S} , one would expect \mathbf{L} to be sufficiently altered to reduce the advantages of our ENSO-removal method over other methods. So far, however, the basic state changes appear to have been small enough to justify our linear decomposition throughout the 136-yr period of record.

Given the evidence of the near-constancy of \mathbf{L} , one might wonder if we could have used the entire 136 year record to construct \mathbf{L} . We found that we could not have, owing to sparse observations in key regions in the early part of the record. For example, we estimated \mathbf{L} using the 1872-1947 data. The optimal final structure $\boldsymbol{\psi}_1$ using these data had a pattern correlation with the $\boldsymbol{\psi}_1$ in Fig. 3b of 0.95. However, $\boldsymbol{\phi}_1$, the optimal initial

structure, had a pattern correlation with the ϕ_1 in Fig. 3a of only 0.25. One could have anticipated this result after considering the data availability in regions in which these structures have large amplitude (Fig. 12). Figure 12a shows the number of SST observations in the ICOADS collection (Worley et al. 2005), which represents a superset of that used to construct the HadISST fields, in March through May in two regions where ϕ_1 has large amplitude. The data availability in March-May is relevant, since this is when most ENSO events emerge (PS95, Harrison and Larkin 1998). There were clearly far fewer observations in these months in these key regions in the late nineteenth and early twentieth centuries. In contrast, the central equatorial Pacific region of large amplitude of ψ_1 was well observed in the mature December-February phase of ENSO throughout the record (Fig. 12b). It was in recognition of such constraints on data availability that we decided to estimate \mathbf{L} using the more recent 1949-2004 period, in which there were sufficient observations to determine both ϕ_1 and ψ_1 with sufficient accuracy.

6. Summary and Conclusions

In this paper, we argued that identifying and removing ENSO-related variations by performing regressions on any single ENSO index can be problematic. We stressed that ENSO is best viewed not as a *number* but as an evolving dynamical *process* for this purpose. Specifically, we identified ENSO with those four dynamical eigenvectors of tropical SST evolution that are most important in the observed evolution of ENSO events over several seasons. We used this definition to isolate the ENSO-related component of global SST variations on a month-by-month basis in the 136-yr (1871-2006) HadISST dataset.

We find that removing ENSO-related variations has a large effect on long-term SST trends and on the dominant patterns of low-frequency (5-yr running mean) SST variability. We interpret the low-frequency ENSO-unrelated SST variations as reflecting an as yet undetermined combination of anthropogenic, naturally forced, and coherent internal multi-decadal variations. The 1st EOF of the ENSO-unrelated data has a general “global warming” structure, but also a pronounced *cooling* in the eastern equatorial Pacific, which, although surprising, is not unphysical. The 2nd EOF is strongly suggestive of a multi-decadal zonally symmetric Tropical-Extratropical SST seesaw (TESS) pattern. It is not clear to what extent it reflects a pattern of forced or natural variability. We are more inclined towards interpreting it as the latter, given that the amplitude time series of this pattern has no trend over the last 136 years.

It is important to recognize that our decomposition of the low-frequency SST fields into ENSO-unrelated and ENSO-related parts is not strictly the same as into "predictable" and "unpredictable" parts. The ENSO-unrelated parts may be predictable if the relevant anthropogenic and natural radiative forcings are predictable and the appropriate initial conditions for coherent internal long-term variations are known. The ENSO-related parts, as identified by us, include both the unpredictable "low-frequency tail" of ENSO and the potentially predictable projection of anthropogenic and naturally forced SST variations on the 8 ENSO mode patterns in Fig. 4. In other words, our ENSO-unrelated low-frequency fields may be mostly predictable, but our ENSO-related fields may not be totally unpredictable. The latter remark applies equally, of course, to any other pattern-

based method of identifying ENSO-related climate variations. One way of assessing the contribution of the unpredictable "low-frequency tail" to our estimated ENSO-related trends and ENSO-related low-frequency variations is to make very long runs of the model (3) and determine its spectrum at low frequencies. This is a topic of current research.

Regardless of the relative magnitudes of the potentially predictable "forced" and unpredictable "low-frequency tail" portions of our estimated ENSO-related variations, the very existence of an unpredictable portion makes it inappropriate to compare climate model simulations of SST variations over the last 136 years with the observed SSTs variations. It may be more appropriate to compare just their simulated ENSO-unrelated portions with the corresponding observed ENSO-unrelated portions estimated here. Finally, although one should not expect climate models to simulate the precise time series of the observed ENSO-related variations, one should expect their ENSO modes to match those in Fig. 4. This is necessary for correctly representing the statistics of ENSO-related climate variability that, even if it is partly just "noise", can nevertheless modulate climate changes around the globe.

Acknowledgments: We thank our colleagues in the Climate Dynamics Center of CIRES/CU and in the Physical Sciences Division of ESRL/NOAA, especially C. Penland and M. Alexander for useful discussions and C. Smith for help with the SST data. We thank C. Folland of the UK Met Office for discussions regarding the AMO. We thank the UK Met Office Hadley Centre, N. Rayner and BADC for providing the HadISST data.

Figure Captions

Figure 1. Time series of the global ocean average anomaly (black curve) and its ENSO-unrelated component determined using the ENSO Patterns Filter (red curve). A 10-year running mean has been applied to both series. Anomalies are relative to a 1949-2004 climatology.

Figure 2. Maps of the local anomaly correlation between observed and predicted seasonal SST anomalies using the Linear Inverse Model prediction equation (3). Maps are shown for lead times of (a) 3 months, (b) 6 months, (c) 9 months, and (d) 12 months. Correlations are computed over the period 1949-2004. The contour interval is 0.2, with a 0.95 contour added.

Figure 3. (a) The optimal initial SST anomaly structure evolves into (b) the optimal “final” structure after 8 months. Each field is normalized to unity. Contour interval is 0.005. Shading is arbitrary and is the same sign in both panels. (c) Gray curve: time series of the projection of the optimal initial structure onto the observed SST anomalies; Black curve: Niño-3.4 time series shifted backwards 8 months. Both series have been normalized by their respective standard deviations. The correlation between the gray and black series is 0.65.

Figure 4. (Left panels) Least energetic and (right panels) most energetic phases of the four dynamical ENSO modes used for defining the ENSO-related tropical SST variations. The modes are ordered according to the projection of their adjoint onto the optimal initial

structure shown in Fig. 3a. Each mode's effective timescale $1/|\beta|$ is indicated. Each mode evolves from the least energetic phase **a** (left panels) to the most energetic phase **b** (right panels), then to $-\mathbf{a}$, and then to $-\mathbf{b}$ with the indicated period $2\pi/\omega$ while decaying with the indicated decay timescale $-1/\sigma$. (left panels) The **a** phase is normalized to unity. Note that the **a** and **b** phases of each mode are orthogonal to each other by construction.

Figure 5. Fraction of variance of band-pass filtered extratropical SST anomalies explained by similarly band-pass filtered tropical SST anomalies using the “atmospheric bridge” operator **A** in the (a) Northern Hemisphere and (b) Southern Hemisphere. All data were bandpass filtered using a Morlet wavelet filter with a response between 2 and 72 months. Contour interval is 0.2.

Figure 6. Global maps of linear trends over 1871-2006 of (a) the full HadISST SST anomalies, (b) the ENSO-related anomalies, and (c) the ENSO-unrelated anomalies. Contour interval is 0.2°C change per 50 years.

Figure 7. As in Fig. 6, but for trends over 1949-2006.

Figure 8. (Left panels) The two leading EOFs and associated principal components (PCs, inset) of 5-year running mean SST anomalies from the 1871-2006 HadISST dataset and (right panels) the same quantities computing using the ENSO-unrelated SST anomalies. The fraction of variance explained is indicated over each panel. Note that the PCs are normalized to have unit amplitude, while the EOFs show the observed magnitude in °C for a unit deviation of the PC. The contour interval is 0.05°C.

Figure 9. (Black curves) Time series of the (a) Warm Pool and (b) Atlantic Multidecadal Oscillation and (red curves) their ENSO-unrelated components. A 10-year running mean has been applied to all series. Anomalies are relative to the 1949-2004 climatology. Area averages are computed over the regions indicated on the respective inset maps.

Figure 10. (Top panel) Time series of east-west and north-south Pacific SST differences scaled by their respective longterm mean values. Black curve: temperature difference between Niño-3.4 and western Pacific warm pool ΔT_{E-W} . The 1871-2006 mean difference is -1.98°C. Blue curve: temperature difference between the north subtropical and tropical Pacific ΔT_{N-S} . The 1871-2006 difference is -1.74°C. A 10-year running averaged has been applied to the difference series. Regions are shown on the inset map. (Lower panel) Gray shaded curve: variance of Niño-3.4 SST anomalies in the 2 to 6 year band determined from wavelet analysis.

Figure 11. Time series of the pattern correlation between forecast and observed tropical SST anomaly fields from 1871-2006. Forecast skill is shown for leads of (red curve) 3

months, (blue curve) 6 months, and (pink curve) 12 months. A 10 year running mean has been applied. Gray shading indicates the 95% range of expected fluctuations about the 1949-2004 mean value at each lag.

Figure 12. Time series of the number of SST observations available in the ICOADS collection for selected seasons and regions from 1871-2006. (a) During March through May in two regions of large loading of the optimal initial structure [see inset (10°N - 3°N , 140°E - 165°W); (22°S - 30°S , 160°W - 105°W)]. (b) During December through February in the region of large loading of the optimal evolved structure [see inset (6°N - 7°S , 180° - 85°W)]. The number of observations is shown on a logarithmic scale. The thin line in both panels indicates 500 SST observations per season.

Figure 1. Time series of the global ocean average anomaly (black curve) and its ENSO-unrelated component determined using the ENSO Patterns Filter (red curve). A 10-year running mean has been applied to both series. Anomalies are relative to a 1949-2004 climatology.

Anomaly Correlation Predicting Tropical SST (1949-2004)

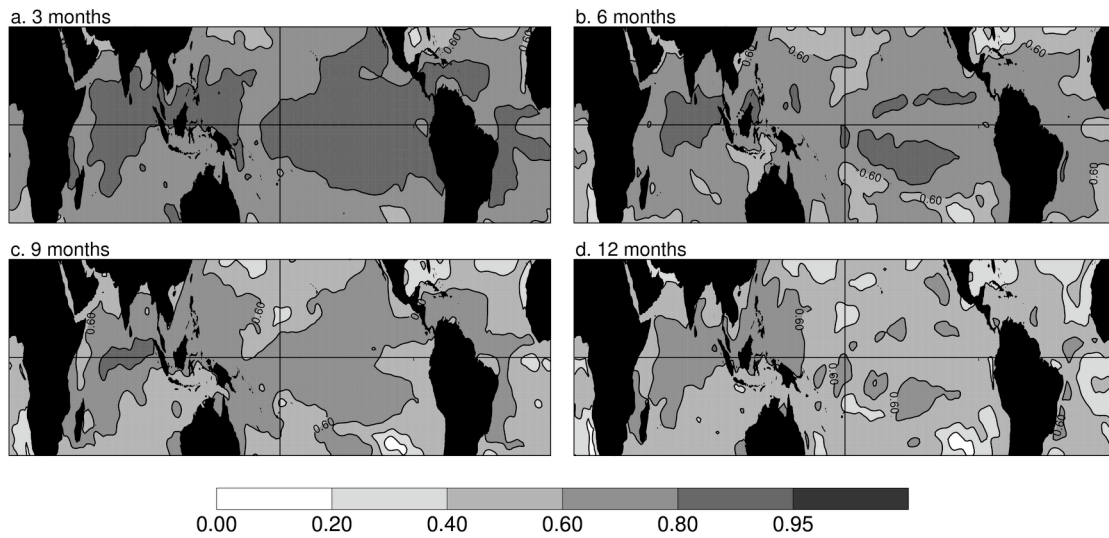

Figure 2. Maps of the local anomaly correlation between observed and predicted seasonal SST anomalies using the Linear Inverse Model prediction equation (3). Maps are shown for lead times of (a) 3 months, (b) 6 months, (c) 9 months, and (d) 12 months. Correlations are computed over the period 1949-2004. The contour interval is 0.2, with a 0.95 contour added.

Figure 3. (a) The optimal initial SST anomaly structure evolves into (b) the optimal “final” structure after 8 months. Each field is normalized to unity. Contour interval is 0.005. Shading is arbitrary and is the same sign in both panels. (c) Gray curve: time series of the projection of the optimal initial structure onto the observed SST anomalies; Black curve: Niño-3.4 time series shifted backwards 8 months. Both series have been normalized by their respective standard deviations. The correlation between the gray and black series is 0.65.

(left panels) The **a** phase is normalized to unity. Note that the **a** and **b** phases of each mode are orthogonal to each other by construction.

Interannual Extratropical SST Variance Explained by Tropical SST

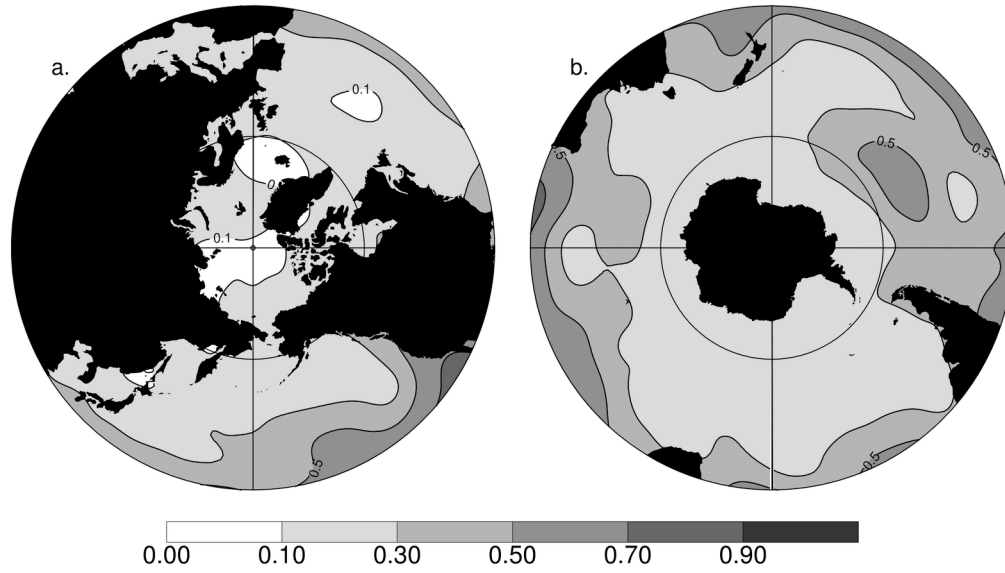

Figure 5. Fraction of variance of band-pass filtered extratropical SST anomalies explained by similarly band-pass filtered tropical SST anomalies using the “atmospheric bridge” operator \mathbf{A} in the (a) Northern Hemisphere and (b) Southern Hemisphere. All data were bandpass filtered using a Morlet wavelet filter with a response between 2 and 72 months. Contour interval is 0.2.

(a) Observed trend of Global Sea Surface Temperature (1871-2006) $^{\circ}\text{C}/50\text{ yr}$

(b) ENSO-related component of observed trend

(c) ENSO-unrelated component of observed trend

Figure 6. Global maps of linear trends over 1871-2006 of (a) the full HadISST SST anomalies, (b) the ENSO-related anomalies, and (c) the ENSO-unrelated anomalies. Contour interval is 0.2°C change per 50 years.

(a) Observed trend of Global Sea Surface Temperature (1949-2006) $^{\circ}\text{C}/50\text{ yr}$

(b) ENSO-related component of observed trend

(c) ENSO-unrelated component of observed trend

Figure 7. As in Fig. 6 but for trends over 1949-2006.

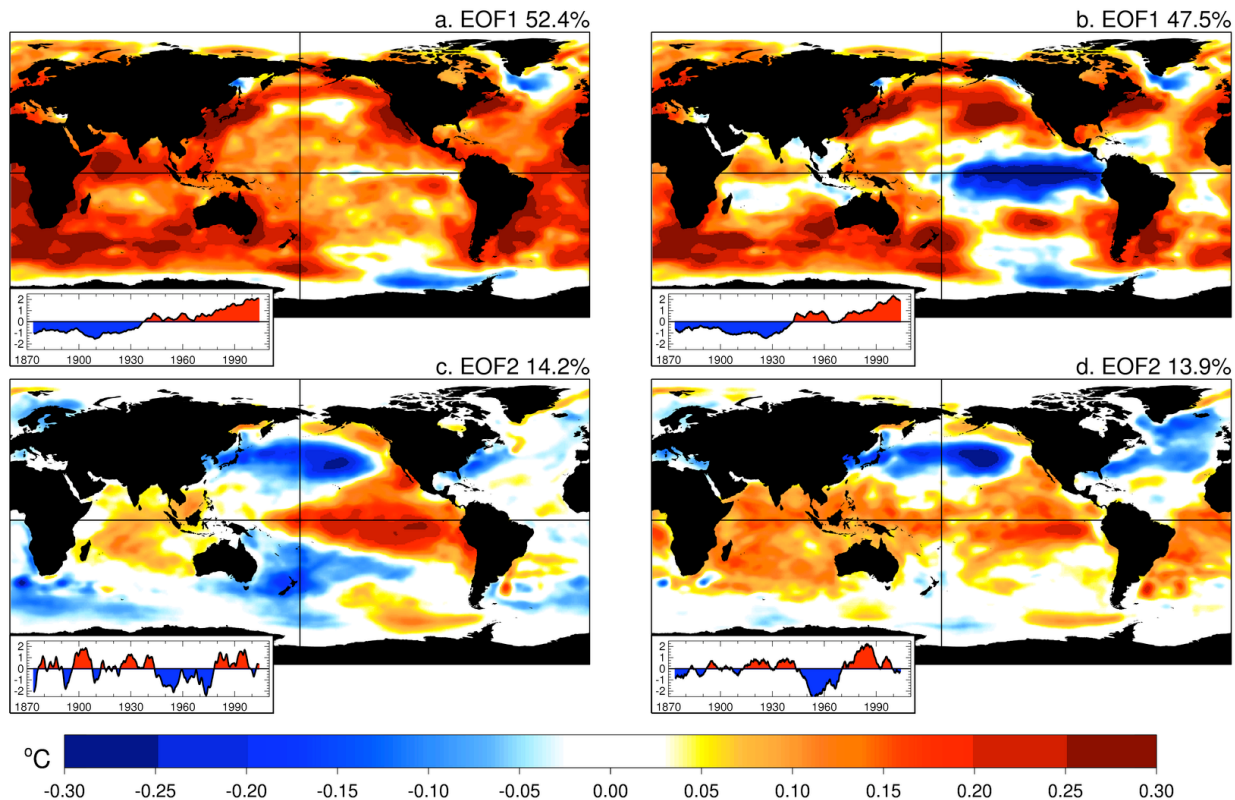

Figure 8. (Left panels) The two leading EOFs and associated principal components (PCs, inset) of 5-year running mean SST anomalies from the 1871-2006 HadISST dataset and (right panels) the same quantities computing using the ENSO-unrelated SST anomalies. The fraction of variance explained is indicated over each panel. Note that the PCs are normalized to have unit amplitude, while the EOFs show the observed magnitude in $^{\circ}\text{C}$ for a unit deviation of the PC. The contour interval is 0.05°C .

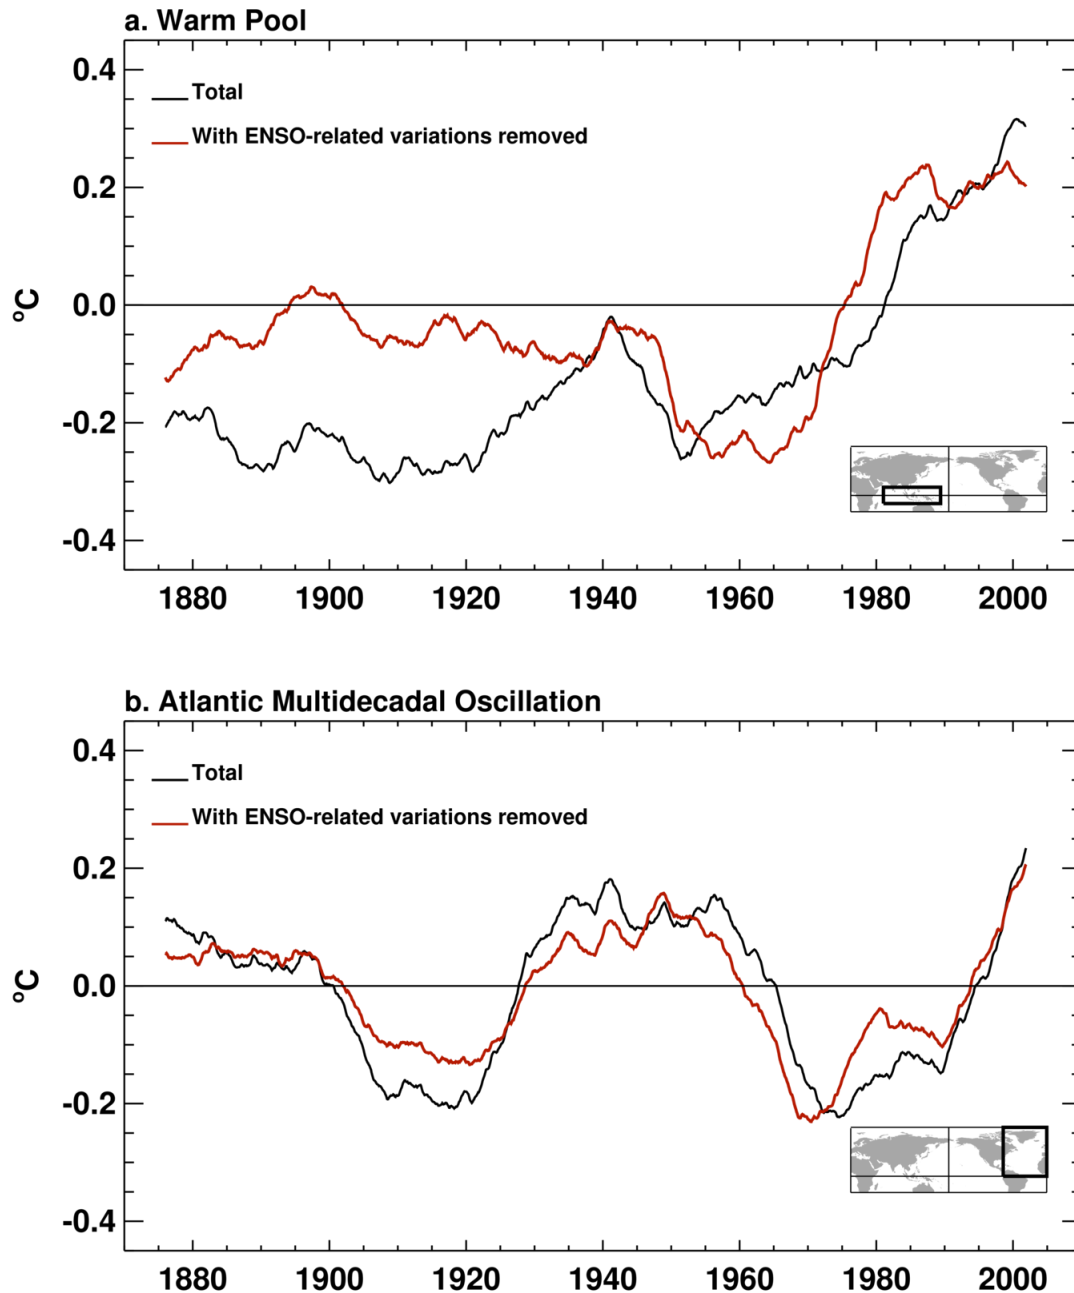

Figure 9. (Black curves) Time series of the (a) Warm Pool and (b) Atlantic Multidecadal Oscillation and (red curves) their ENSO-unrelated components. A 10-year running mean has been applied to all series. Anomalies are relative to the 1949-2004 climatology. Area averages are computed over the regions indicated on the respective inset maps.

Figure 10. (Top panel) Time series of east-west and north-south Pacific SST differences scaled by their respective longterm mean values. Black curve: temperature difference between Niño3.4 and western Pacific warm pool ΔT_{E-W} . The 1871-2006 mean difference is -1.98°C . Blue curve: temperature difference between the north subtropical and tropical Pacific ΔT_{N-S} . The 1871-2006 difference is -1.74°C . A 10-year running averaged has been applied to the difference series. Regions are shown on the inset map. (Lower panel) Gray shaded curve: variance of Niño3.4 SST anomalies in the 2 to 6 year band determined from wavelet analysis.

Figure 11. Time series of the pattern correlation between forecast and observed tropical SST anomaly fields from 1871-2006. Forecast skill is shown for leads of (red curve) 3 months, (blue curve) 6 months, and (pink curve) 12 months. A 10 year running mean has been applied. Gray shading indicates the 95% range of expected fluctuations about the 1949-2004 mean value at each lag.

Figure 12. Time series of the number of SST observations available in the ICOADS collection for selected seasons and regions from 1871-2006. (a) During March through May in two regions of large loading of the optimal initial structure [see inset (10°N - 3°N , 140°E - 165°W); (22°S - 30°S , 160°W - 105°W)]. (b) During December through February in the region of large loading of the optimal evolved structure [see inset (6°N - 7°S , 180° - 85°W)]. The number of observations is shown on a logarithmic scale. The thin line in both panels indicates 500 SST observations per season.
